Abstract

Weak oral bacteria such as periodontal bacteria have been observed in various arterial and venous lesions with epidemiological data reported prior to the discovery of bacterial invasion into vessels. Rich lymph vessels easily bring the bacteria to the neck and the venous angle, which is directly open to the blood vessels. Periodontal bacteria travel within platelets. Periodontal bacteria, especially P. gingivalis aggregates platelets and forms thrombus. At the same time, secretions such as serotonin, various cytokines, and adhesion factors also appear in the blood. The characteristic of the arterial lesions are dependent on the age of the patient and the condition of the endothelial cells. In young patients, infectious incidents occur due to embolic mechanisms in Buerger disease or adherence to the superficial veins valves in varicose veins. In aged patients, incidents result in adhesion in the proximal, acute, coronary arteries or large arteries. The hypotheses here unify the evidence or vessel lesion development and explain possible discrepancy between vascular diseases. We were able to emphasize the collaboration study in this study with dentists and vascular surgeons.

Keywords: Dentist; Vascular surgeon; Weak oral bacteria; Buerger disease; Transportation of oral bacteria; Oral care

Introduction

Since 1999, various weak oral bacteria have been identified in atherosclerotic lesions [1]. Among these bacteria, Chlamydia pneumoniae which resides in the mouth, pharynx, or bronchus, has been thoroughly investigated and confirmed to be transported to vessel walls by monocytes [2]. This invasion mechanism appears to be a factor in the development of atherosclerosis. Additionally, cytomegalovirus can be absorbed from the oral cavity resulting in opportunistic infections. Recently, the so called inflammatory abdominal aortic aneurysmal walls revealed the presence of cytomegalovirus [3]. Helicobacter pylori is well-known bacteria that resides in the stomach and may also appear in the oral cavity. This one was also identified in vessel walls. Over the past 13 years, the periodontal bacteria group that includes several species has been shown within vessel walls [4-6]. We, dentists and surgeons, started a study about periodontal bacteria invading the vessels in which we clarified the relationship between periodontal bacteria and vascular diseases, especially Buerger disease, which is still major vascular disease in south and western Asia [7].

Details of Buerger Disease Infection Theory

Many investigators, including Leo Buerger, believed that Buerger disease is an infectious disease [8]. They studied actual cases and conducted animal experiments, but nobody could find the pathogen. In 1928, Professor Allen of the Mayo Clinic was also suspicious about oral bacteria as a cause and mentioned that 75% of 87 Buerger disease sufferers showed periodontal infection and 80% showed tonsil enlargement or pus attachment [9]. Allen believed that Buerger disease was an infectious disease until he died in 1967. After his death, however, Buerger disease was classified as an inflammatory autoimmune disease.

Clinical diagnosis of Buerger disease is made using Shionoya's criteria, namely 1) young heavy smoker under 50 years of age, 2) lower leg arterial occlusion, 3) phlebitis migrans or upper extremities arterial occlusion, 4) no risk factors for atherosclerosis except smoking. There are about 8000 persons registered in Japan. Thus, the total number of patients in Asia is estimated one million.

Periodontal Bacterial Invasion to the Arterial Wall and Thrombus

Because periodontal bacteria are not detectable with the usual cultures, they are extremely difficult to identify. Most periodontal bacteria are anaerobic and were difficult to detect by cultural method in 1960s but after the development of anaerobic culturing, the cultural detection of periodontal bacteria is not difficult. These includes more than 300 species overall. Usually 6-7 species are examined as representative bacteria nowadays. Therefore the established PCR (polymerase chain reaction) method to detect the DNA of the oral bacteria has become popular [10].

Until now, periodontal bacterial DNA was detected from carotid arterial plaques, coronary arterial plaques, abdominal aortic aneurysmal walls (86% of patients) and intraluminal thrombi (88%), atherosclerotic vessel plaques (52%), occluded arteries of Buerger disease patients (93%), migrating phlebitis samples (2 cases, 100%), and primary varicose veins (48%) [4-6]. In these studies, specimen were obtained from the vascular surgical unit and stored at -80°C. These specimens were then moved to be examined in the periodontal unit laboratory of the same university.

How are the Bacteria Transported to the Vessel Wall?

Our results using rats after continuous intravenous oral bacterial infusion showed newly formed thrombus in the small arteries of the extremities with 50% of the specimens having bacterial DNA [11].

In 2004, we, vascular surgeons, began using the Platelets Rich...
Plasma (PRP) to stimulate good wound healing. When we accidentally added periodontal bacteria (*P. gingivalis*) to the sample and saw the mixed fluid through a stereoscopic microscope, we could find active movement. After examining the sample by electron microscopy, we observed that periodontal bacteria (*P. gingivalis*) were engulfed by platelets and morphologically there were no change observed in the bacteria for one hour. Additionally, platelet aggregation was also observed. These observations confirmed that *P. gingivalis* bacteria aggregate strongly in the platelets, and they don’t die (Figure 1) [12].

*P. gingivalis* induced platelet aggregation reached the maximum in a few minutes and the mass became more than 20 microns larger than the size of the small artery in vitro. Additionally, as periodontitis itself expresses inflammatory substances such as IL-6, and TNFα, it should be considered a systemic disorder [13]. A strong relationship with diabetes mellitus control is coming from the abovementioned mechanism. Fortunately, for our healthcare is now associated with good social manners.

**Serum Bacterial Antibody Titer Changes in Periodontal Disease and Buerger Disease**

Chen et al. [14] who are dentists, reported that the antibody titer for periodontal bacteria is significantly elevated in Buerger disease patients, reconfirming that Buerger disease patients have very poor periodontal conditions [5] (Figure 2). In Buerger disease the antibody titers may actually be changing related to the severity of periodontitis. Effective antibiotic treatment against the bacteria can decrease the titer level rapidly.

**Do All Persons with Serious Periodontitis Develop Buerger Disease or another Vascular Arterial Disorder?**

Recent studies on Buerger disease have shown a specific HLA locus and infection susceptibility for basilar bacteria, such as periodontal bacteria [15]. Varicose veins seem to occur in mothers and daughters. Interestingly approximately 50% of varicose veins contain periodontal bacterial DNA by our study suggesting that pregnancy may be linked to varicosity development when the woman suffers from periodontitis during pregnancy. However it is questionable that the periodontal bacteria may transmit from mothers to daughters.

**Hypothesis and Future Views of Buerger Disease Development**

Pathogens in Buerger disease are likely to be mainly periodontal bacteria. Among periodontal bacteria, *T. denticola* and *P. gingivalis* are main member of red complex, bacterial group characteristic of periodontitis patients. *P. gingivalis* is inevitably moved as an initiator of platelet aggregation, and from the venous angle of the neck, the bacteria group can enter the blood stream and stimulate platelet aggregation after uptake into platelets. It is suggested that aggregation reaches a maximum level when the platelet thrombi passes through the lung, after which the thrombi starts to move in the arterial blood stream. When the arterial wall is young but spastic from cigarette smoking, the platelet thrombus containing the oral bacteria do not adhere to the arterial wall but form a small arterial embolism. It is suggested that the digital arterial obstruction in Buerger disease patient angiography may be initial findings. This change will grow to the proximal arterial regions due to packing. Microorganisms that pass through capillaries can be caught at the venous valves, resulting in phlebitis migrans or deep vein thrombosis formation in the extremities. The literature shows small arterial changes are very common all over the body, but are symptomatic only in the extremities (Figure 3). This mechanism is specific in Buerger disease and considerably different from atherosclerotic disease including aneurysms [16,17].

---

**Figure 1:** Platelets may play a vital role in the transportation of the oral bacteria. *P. gingivalis* is a round shaped mass.

**Figure 2:** Oral condition of Buerger disease patients. A: 34-year old male; B: 55-year-old male, with no fingers and right below-knee amputation.

**Figure 3:** Hypothesis of Buerger disease development. This is different from the developing mechanism of atherosclerosis. From the literature 17.
